Received 26 August 1986

The use of new  $^1\text{H}$ -detected heteronuclear  $^1\text{H}$ - $^{31}\text{P}$  shift correlation experiments is demonstrated for oligonucleotides of 12 and 40 base pairs. The methods give unambiguous assignments of the  $^{31}\text{P}$  resonances and also permit identification of the C4' and C5' sugar protons. Use of the new methods enables one to make sequence-specific resonance assignments without reference to a known or assumed conformation of the DNA fragment.

## 1. INTRODUCTION

$^{31}\text{P}$  NMR can provide important structural and dynamic information on nucleic acids [1]. A problem in using this information originates in the difficulty of resolving and assigning the individual resonances in the  $^{31}\text{P}$  NMR spectra. So far, application of modern 2D NMR methods to solving this problem has been limited to the study of relatively small oligonucleotide sequences [2–4]. Here it is demonstrated that  $^1\text{H}$ -detected correlation techniques can be used successfully to correlate  $^1\text{H}$  and  $^{31}\text{P}$  chemical shifts for oligonucleotides of up to 40 base pairs.  $^1\text{H}$ -detected heteronuclear shift correlation techniques have recently been shown to provide a gain in sensitivity of one to two orders of magnitude when applied to

the study of  $^{13}\text{C}$  and  $^{15}\text{N}$  [5,6]. For  $^{31}\text{P}$  NMR, this gain in sensitivity is substantially lower because of the relatively high magnetogyric ratio of  $^{31}\text{P}$ . Nevertheless, a gain in sensitivity by a factor of about three is easily obtainable over 2D experiments that employ direct  $^{31}\text{P}$  detection.

## 2. METHODS AND RESULTS

Two slightly different schemes have been used in the present study and are sketched in fig.1. The scheme of fig.1a provides a 2D absorption mode spectrum and consequently offers the highest spectral resolution. The scheme of fig.1b utilizes the 'constant-time concept' [7,8], optimizing magnetization transfer from  $^{31}\text{P}$  to  $^1\text{H}$  and maximizing sensitivity of the method. First we will discuss the application of scheme 1a to the study of the dodecamer d(CATGGATm<sup>5</sup>CCATG) duplex. Rather than transferring  $^1\text{H}$  magnetization into  $^1\text{H}$ - $^{31}\text{P}$  multiple quantum coherence [2,3] we prefer to start with  $^{31}\text{P}$  magnetization directly. In principle, one would expect a loss in sensitivity by a factor of  $\gamma_{\text{H}}/\gamma_{\text{P}}$  ( $\approx 2.5$ ) of scheme 1a vs the multiple quantum experiment. However, generating the

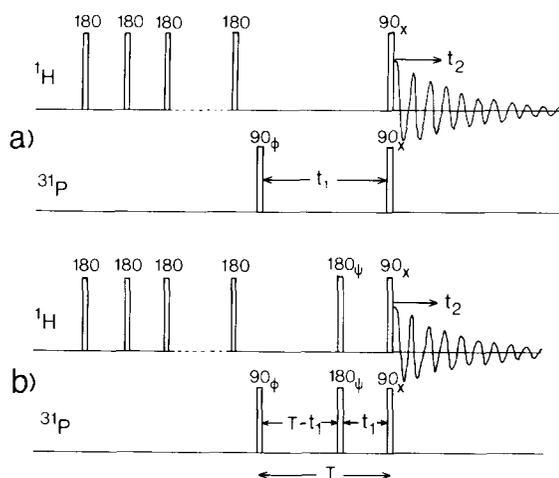

Fig.1. Pulse schemes for generating 2D  $^1\text{H}$ - $^{31}\text{P}$  correlation spectra. During the delay period between consecutive scans, both schemes use a series of 40  $180^\circ$  pulses, spaced by 50 ms, to presaturate  $^1\text{H}$  resonances. In both schemes, the phase  $\phi$  of the first  $^{31}\text{P}$  pulse is cycled  $x, y, -x, -y$  and the receiver is cycled  $x, -x, x, -x$ . In addition, the phase  $\psi$  of the  $180^\circ$  pulses in scheme b is incremented by  $90^\circ$  every 32 scans; furthermore, each time  $\psi$  is incremented, the phase of the receiver is inverted. Data in odd- and even-numbered scans are stored separately and processed in the standard manner to separate positive and negative modulation frequencies. Scheme a results in a 2D pure absorption spectrum whereas scheme b requires an absolute value mode calculation in the  $t_1$  dimension. Dispersive data in the  $t_2$  dimension are discarded after the first Fourier transformation and the final spectrum is absorptive in this dimension.

$^1\text{H}$ - $^{31}\text{P}$  multiple quantum coherence is not an effective process and in practice scheme 1a appears to be more efficient. The detected  $^1\text{H}$  magnetization transferred from  $^{31}\text{P}$  at  $t_2 = 0$  is in antiphase with respect to  $^{31}\text{P}$  but in phase with respect to all other protons. Absorption mode 2D spectra can therefore be recorded readily without the need for  $z$  filters or purge pulses [2]. Signals that do not originate from transfer from  $^{31}\text{P}$  are suppressed by phase cycling and by presaturation of the  $^1\text{H}$  signals using a series of  $180^\circ$  pulses in between experiments.

Fig.2 shows the 2D correlation spectrum of the dodecamer. In addition to the expected three-bond connectivities to H3' and H5', H5'' also all of the four-bond H4'-C4'-C5'-O-P connectivities are

observed. Since most of the C4' protons are resolved and assignable by means of a 2D NOE experiment, sequential assignment information follows directly from this type of spectrum. We have found the presence of P-H4' connectivity in all other oligonucleotides studied with this method so far. It may therefore be expected that this important connectivity is a general feature observed in this type of spectrum.

In scheme 1a, the amount of  $^{31}\text{P}$  magnetization transferred to  $^1\text{H}$  is a function of the length of the evolution period,  $t_1$ . The  $t_1$  duration for which maximum transfer occurs depends on the sizes of the  $J_{\text{HP}}$  couplings and on the  $^{31}\text{P}$  transverse relaxation time. In practice, a maximum is reached for a  $t_1$  duration of about 25 ms. Scheme 1b exploits this fact by keeping the length of the evolution period fixed to a time,  $T$  ( $\approx 25$  ms), and moving the pair of  $^1\text{H}/^{31}\text{P}$   $180^\circ$  pulses stepwise through this period. This makes it appear as if the evolution period is varied from  $-T$  to  $+T$ , i.e. it gives an effective acquisition time of  $2T$  in the  $t_1$  dimension. Note that the detected  $^1\text{H}$  signals are modulated as a function of  $t_1$  only by the  $^{31}\text{P}$  chemical shifts and not by scalar coupling, providing the highest possible resolution in the  $t_1$  dimension. Unfortunately, the overall duration of the apparent length of the evolution period is limited to  $2T$ , which limits the final resolution obtainable. However, use of the modern maximum entropy type processing methods may significantly alleviate this problem [9]. As an example, fig.3 shows the  $^1\text{H}$ - $^{31}\text{P}$  correlation spectrum of the synthetic DNA oligomer d(TA)<sub>20</sub>. Although both the  $^1\text{H}$  and the  $^{31}\text{P}$  linewidths are relatively broad for this large fragment, a clear correlation for both  $^{31}\text{P}$  resonances is observed. This spectrum confirms the previously made assignment of the  $^{31}\text{P}$  resonances, made by comparison with two phosphorothioate analogues [10].

### 3. DISCUSSION

We have shown that the  $^1\text{H}$ - $^{31}\text{P}$  correlation method can be applied successfully to the study of DNA fragments of a significant size, requiring only moderate NMR sample quantities. Not only does this type of experiment make it possible to obtain an unambiguous assignment of the  $^{31}\text{P}$  spectrum, important for structural studies, but it also

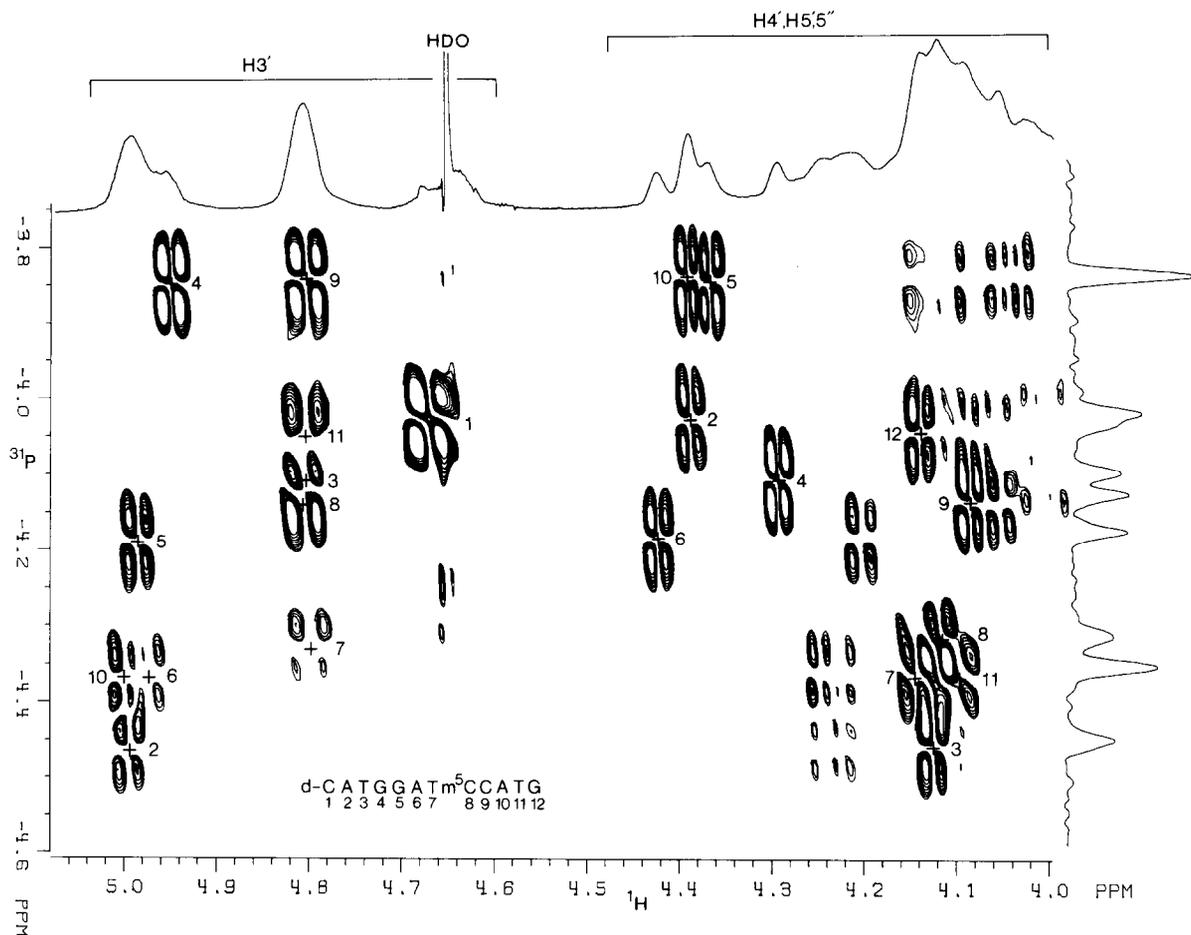

Fig.2. 2D absorption mode  $^1\text{H}$ - $^{31}\text{P}$  correlation spectrum of the dodecamer d(CATGGATm<sup>5</sup>CCATG), recorded with the scheme of fig.1a.  $^1\text{H}$  and  $^{31}\text{P}$  chemical shifts are relative to TSP and TMP, respectively. The spectrum results from a  $2 \times 64 \times 1024$  data matrix with 80 scans per  $t_1$  value. Acquisition times in the  $t_1$  and  $t_2$  dimension are 0.128 and 1.02 s, respectively. The total measuring time is 8 h. Both negative and positive contours are shown and resolution-enhanced 1D  $^1\text{H}$  and  $^{31}\text{P}$  spectra are shown along the two axes of the 2D spectrum. 8 Hz Gaussian broadening is used in the  $t_2$  dimension and 9 Hz exponential narrowing followed by 12 Hz Gaussian broadening is used in the  $t_1$  dimension. The centers of the correlation multiplets are marked + and only correlations with H3' and H4' protons are labeled.

provides a means to make sequence-specific resonance assignments independent of an assumed structure of the DNA fragment. The high intensity of the H4'-P correlations suggests a coupling constant larger than the 2 Hz previously estimated [11]. The relatively long transverse relaxation time of the C4' protons also contributes favorably to the intensity of these cross-peaks.

#### 4. EXPERIMENTAL

The dodecamer was synthesized manually by the

solid-phase phosphite triester method using the *O*- $\beta$ -cyanoethylphosphoramidites. 600  $A_{260}$  units were dissolved in 0.4 ml  $\text{D}_2\text{O}$ , containing 0.1 M NaCl, 10 mM sodium phosphate,  $\text{p}^2\text{H}$  7.4. The spectrum of fig.2 was recorded at 35°C.

The 5'-dimethoxytrityl (DMT) derivative of the self-complementary 40-mer, d(TA)<sub>20</sub>, was synthesized on a  $2 \times 1$ - $\mu\text{mol}$  scale using a previously described [12] automated (Applied Biosystems model 380B) version of the phosphoramidite coupling method, with the exceptions that *O*- $\beta$ -cyanoethylamidites were employed, and deprotec-

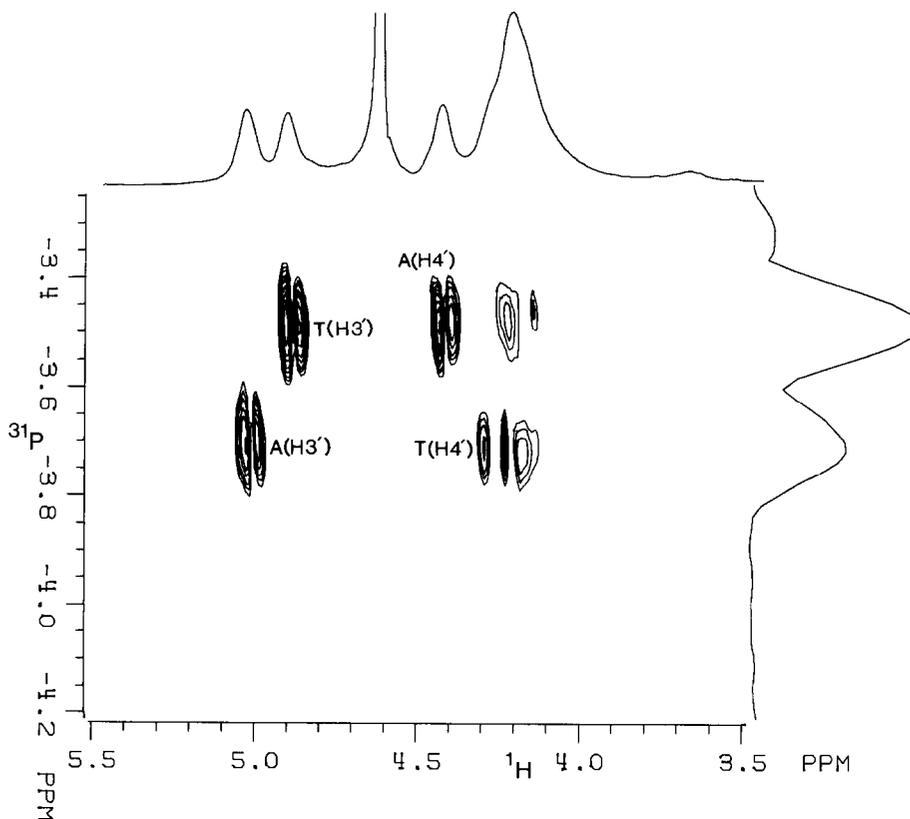

Fig.3. 2D correlation spectrum of the 40-mer  $d(TA)_{20}$ , recorded with the scheme of fig.1b. The spectrum is absorptive in the  $^1H$  dimension but in the absolute value mode in the  $^{31}P$  dimension.  $^1H$  and  $^{31}P$  chemical shifts are relative to TSP and sodium phosphate, respectively. The spectrum results from a  $2 \times 50 \times 512$  data matrix, with the effective  $t_1$  acquisition period ranging from  $-25$  to  $+25$  ms and the  $t_2$  acquisition period from 0 to 108 ms. The  $^{31}P$   $T_1$  (1.4 s) was shorter than the  $^1H$   $T_1$  ( $\approx 2$  s), and a 2-s delay between scans was used. The total measuring time was 12 h. The resolution-enhanced  $^1H$  spectrum and the projection of the 2D spectrum on the  $^{31}P$  axis are shown along the sides of the 2D spectrum.

tion with thiophenol-triethylamine was omitted. The crude 5'-DMT material obtained from the parallel syntheses was pooled and dissolved in 12 ml of 0.1 M triethylammonium acetate (pH 7, TEAA). Four equal-volume portions of the resultant solution were each eluted from a reversed-phase HPLC column (Hamilton PRP-1,  $7 \times 305$  mm) with a 1%/min gradient of acetonitrile in 0.1 M TEAA (pH 7) that began and ended at acetonitrile-TEAA ratios of 20:80 and 30:70, respectively [13]. The center-cut fractions which were collected at 10.5–11.5 min were pooled, lyophilized, detritylated, lyophilized, dissolved in

1 ml of 0.2 M NaCl, and then eluted with water from a size-exclusion column (Sephadex G-25M PD-10) to yield the sodium form of  $d(TA)_{20}$  (105  $A_{260}$  units, 12.5% yield based on support-bound nucleoside). The sample was dissolved in 0.4 ml  $D_2O$ , containing 0.1 M NaCl, 10 mM sodium phosphate, p $^2H$  7.2. The NMR spectrum was recorded at 45°C.

NMR spectra were recorded on a modified Nicolet NT-500 spectrometer equipped with a Cryomagnet Systems 5-mm  $^1H$  probe that has a broad-band ( $^{15}N$ - $^{31}P$ ) decoupling coil for irradiation of low-gamma nuclei.
